## **Introduction to Program Analysis**

Isaac Griffith

CS 4423 and CS 5523 Department of Computer Science Idaho State University

## **Outline**

- Verification: semantics and properties
- 2 Undecidability
- 3 Approaches to program verification
- 4 Outline

## **Verification: a first definition**

In this course, we consider how to **verify specific properties about program executions**:

- absence of execution errors
  - i.e., crashes due to pointer or arithmetic errors
- preservation of invariants
- termination
- absence of information flows and other security breaches...

## **Verification: a first definition**

We are not interested in purely syntactic properties

### Verification

Make sure that  $\llbracket P \rrbracket \subseteq \mathcal{S}$  where

- the semantics  $\llbracket P \rrbracket$  describes the set of behaviors P,
- the specification S describes the set of acceptable behaviors

Behaviors are still an abstract notion at this point

#### Idah Univ

# Idaho Sta Universit Semantics and semantic properties Computer Science Semantics and semantic properties

There exists **several forms of semantics** [P] that convey:

 reachable states, input/output relations (e.g., described by a function), execution traces of program states (finite, infinite, or both)

We will consider two styles of semantics:

- compositional style ("denotational")
  - intuitively,  $\llbracket AB \rrbracket = \dots \llbracket A \rrbracket \dots \llbracket B \rrbracket \dots$
- transitional style ("operational")
  - intuitively,  $[AB] = s_0 \hookrightarrow s_1 \hookrightarrow \ldots, \ldots$
- A right semantics style facilitates the design of static analysis

# Semantics and semantic properties

Specification (or semantic properties of interest):

- sets of executions (that are considered to satisfy a specification)
- property can be expressed by  $\llbracket P \rrbracket \subseteq \mathcal{S}$
- there exist several interesting classes of semantic properties

# **Safety**

### Intuitive definition: safety

A safety property asserts that some kind of behaviors that are observable in finite time will never occur.

#### **Examples**:

- absence of some class of crashing error
  - e.g., null pointer exception in Java, arithmetic or memory error in C
- preservation of a general invariant
  - e.g., some data structure should never get broken
- assertion on output value
  - e.g., the output value of a function should always lie in a given range

#### Proof method: by invariance

• i.e., a safety property  $\mathcal S$  holds if and only if there exists a program **invariant** stronger than  $\mathcal S$ 

## Liveness

### Intuitive definition: liveness

A liveness property asserts that some kind of behaviors that are only observable in infinite time will never occur.

### **Examples:**

- non-termination
- live lock
- unbounded repetition of a given behavior
  - note termination and live-lock are special cases of this one

### Proof method: with a variance argument

- e.g., for termination, ranking functions:
  - search for a measure that decrease during execution and that cannot decrease forever

## **Trace properties**

Not all trace properties are safety or liveness. What about others?

### Theorem (Alpern and Schneider)

Given a trace property  $\mathcal{T}$  (i.e., a set of finite or infinite program executions), then there exists two trace properties  $\mathcal{S}$  and  $\mathcal{L}$  such that:

- $\mathcal{T} = \mathcal{S} \cap \mathcal{L}$
- S is a safety property
- $\mathcal{L}$  is a liveness property

# **Trace properties**

Application: the proof of safety property boils down to

- a proof of safety, by variance
- a proof of liveness, by invariance

**Example**: total correctness = partial correctness and abscence of crashes + termination

How to make such proofs automatic?

# ldaho State University Beyond trace properties: security, dependencies...

Many important semantic properties cannot be described only by a set of executions.

For instance.

- dependence:
  - y depends on x if and only if running the program with distinct values for x yields distinct observations for y
- absence of information flow (security property):
  - absence of dependences of public outputs on private data

To prove/disprove these properties, one needs to reason simultaneiously on pairs of traces

How to make such proofs automatic?

## **Outline**

- 1 Verification: semantics and properties
- 2 Undecidability
- 3 Approaches to program verification
- Outline

## The termination problem

### **Termination**

Program P terminates on input X if and only if any execution of P, with input X eventually reaches a final state

- Final state: final point in the program (i.e., not error)
- We may want to ensure termination:
  - processing of a task, such as, e.g., printing a document
  - computation of a mathematical function
- We may want to ensure non-termination:
  - operating system
  - device drivers

# TP is not computable

- Proof by reductio ad absurdum, using a diagonal argument
  - We assume there exists a program Pa such that:
    - Pa always terminates
    - Pa(P, X) = 1 if P terminates on input X
    - Pa(P, X) = 0 if P does not terminate on input X
- We consider the following program

```
void PO( P ) {
   if ( Pa( P, P ) == 1 ) {
      while ( 1 ) {
            // loop forever
      } else {
        return; // do nothing
      }
   }
}
```

- What is the return value of Pa(P0, P0)?
  - i.e., does P0 terminate on input P0?

# TP is not computable

- What is the return value of Pa(P0, P0)?
  - We know Pa always terminates and returns either 0 or 1 (assumption).
    - if Pa(P0, P0) returns 1, then P0(P0) **loops forever**, thus Pa(P0, P0) should return 0, so we have reached a **contradiction**
    - if Pa(P0, P0) returns 0, then P0(P0) **terminates**, thus Pa(P0, P0) should 1, so we have reached a **contradiction**
- In both cases, we reach a contradiction
- Therefore we conclude no such Pa exists

### TP is not decidable

There exists no program Pt that always terminates and always recognizes whether a program P terminates on input X

# Figure 1 Mario State Verification Problem Undecidability Somputer Computer Computer Verification Problem Undecidability

We assume a turning complete language  ${\mathbb L}$ 

There is no computable algorithm Exact such that

For all 
$$P \in \mathbb{L}$$
, **Exact(** $P$ **)**=  $\llbracket P \rrbracket$ 

Otherwise, we could solve the termination problem by using such Exact.

### Undecidability of non-trivial semantic properties

Let S be a non-trivial semantic property (non-trivial: neither true for all programs nor false for all programs).

Then S is not decidable on L.

# Figure Street Computer Verification Problem Undecidability

There is no fully automatic and exact algorithm deciding S.

#### For instance:

- The halting problem is not decidable
- The absence of runtime errors is not decidable...
- Total correctness is not decidable

## **Outline**

- 1 Verification: semantics and properties
- 2 Undecidability
- **3** Approaches to program verification
- Outline

# Idaho State Present Pr completeness

As we have seen automatic and exact verification is impossible.

How to retain automation, while still verifying programs?

**Approximate verification**, reaches for a **weaker goal** than exact verification

#### Two important notations:

- **Soundness**: analysis(P) = yes  $\Rightarrow$  P satisfies the specification
  - i.e., rejects any program that violates the specification
- Completeness: analysis(P) = ves  $\Leftarrow$ = P satisfies the specification
  - i.e., accepts any program that satisfies the specification

In the following, we consider various verification techniques, that give up partially on either automation, soundness or completeness.

# **Testing**

## Principle |

- Consider finitely many, finite executions
- 2 For each of them, check whether it violates the specification
- Very natural idea, used on all software projects, at all levels (from unit testing to integration testing)
- Many advanced techniques (e.g., to choose "good" test samples)
- Challenging to apply in presence of non-determinism (reproducibility issue) or for hyperproperties (need to talk about several executions in one)...
- In general unsound: when state space is infinite or even finite, but just too big (testing does not scale), soundness cannot be ensured
- Complete: when a violation is discovered, a counter-example can be produced

# Machine assisted proving

## Principle

- Use a specific language to formalize verification goals
- Manually supply proof arguments
- 3 Let the proofs be automatically verified
- Example of tools: Coq, Isabelle/HOL, PVS...
- Applications: CompCert (certified compiler), SeL4 (secure micro-kernel)...
- Not automatic: key proof arguments need to be found by users
- Proof search algorithms often reduce the amount of proof arguments that need to be supplied manually
- Sound, if the formalization is correct
- Quasi-complete (only limited by the expressiveness of the logics)

## Finite state model checking

### Principle

- Focus on finite state models of programs and systems
- 2 Perform exhaustive exploration or some optimised form of it
- Example: Uppaal
- Automatic
- Sound and complete with respect to the model
- However, general programs require approximate models at this stage, one loses either soundness or completeness

## Conservative static analysis

## Principle

- Perform automatic verification, yet which may fail
- Compute a conservative approximation of the program semantics

Two kinds of approximations are possible (with mathematical guarantee):

- Sound, incomplete: the most common case
- Complete, unsound: rare

Sound, incomplete static analysis very widely used:

- Examples: type systems, Astree, Facebook Infer, Sparrow...
- Most compilers use it without users even noticing (type system, analyses for optimization or code generation)
- Automatic
- Incompleteness means that safe programs may be rejected or that false alarms may be raised
- Analysis algorithms reason over program semantics

# **Bug finding**

## Principle

### Automatic, unsound and incomplete algorithms

- Examples: Coverity, CodeSonar...
- Automatic and generally fast
- No mathematical guarantee about the results
  - may reject a correct program, and accept an incorrect one
  - may raise false alarm and fail to report true violations
- Typically used to increase software quality without trying to provide any strong guarantee

# **High-level comparison**

	automatic	sound	complete
testing	yes	no	yes
assisted proving	no	yes	yes/no
model checking of finite state model	yes	yes	yes
model checking, at program level	yes	yes	no
conservative static analysis	yes	yes	no
bug finding	yes	no	no

No program level approach can be automatic, sound and complete

## **Outline**

- 1 Verification: semantics and properties
- 2 Undecidability
- **3** Approaches to program verification
- Outline

# Scope and objectives

We consider **automatic**, **conservative static analyses**, that compute **some abstraction of the semantics of programs** 

To achieve a good understanding of this family of works, we need to study:

- the semantics of programs
  - indeed, it serves as a basis for the definition of abstractions
- the notion of conservative approximation of a semantics
  - i.e., what it means to be conservative, how it can be formalized
- the computation of conservative approximations
  - using abstract interpretation techniques, step-by-step abstract execution, and widening

The lectures focus on foundations (intution and formalization).

The book also exposes advanced topics

We encourage to look at practical chapters (chapter 6 and 7) in the same time as the corresponding notions are considered in the lectures

ROAR

## Outline of the next lectures

- Introduction to static analysis (this course) (chapter 1)
- A gentle introduction to static analysis by abstract interpretation (chapter 2)
- 3 Basic notions of semantics (sections 3.1 and 4.1)
- 4 Semantic abstraction (section 3.2)
- 6 Static analysis based on a compositional semantics
- 6 Static analysis based on a transitional semantics (sections 4.2 and 4.3)
- Specialized static analysis frameworks (chapter 10)
